Abstract: The report provides a description of local damages which are formed in the process of wear-fatigue tests. The analysis of local surface wave-like damages during rolling and mechano-rolling fatigue for the shaft-roller mechanical system under steady-state and multi-stage loading conditions is given. It is shown that the study of local wear-fatigue damage was made possible by new methods of testing and measuring wear-fatigue tests and damages, which are described in the report. New characteristics to estimate the parameters of the local wear-fatigue damage are proposed. The concept of local fatigue curves is introduced. The laws of local wear-fatigue damage for the shaft - roller system are analysed.

Key words: Local Damage, Fatigue, Tribo-Fatigue System, Microcrack, Wear-Fatigue Damage, Residual Deformation, Wave-Like Damage, Troppy Phenomena, Local Fatigue Curve

1. INTRODUCTION

Risk of damage in the small volumes of material is well known to specialists in solid mechanics. Local damages in the form of microcracks, pores, corrosion pits and others lead to a breach of strength at variable loads, and even the complete destruction of structural elements as a result of the merger of microcracks in the main fatigue crack and its development (Fig. 1). Similarly, when the surface of local damage under rolling friction (Fig. 1, 2), sliding or fretting, corrosion the process of gradual degradation of the surface layer of the structural element or component of assembly friction due to damage micro volumes of material, their fusion and development leads to the depletion of the resource of structure or assembly friction (Bayer, 2004; Engel and Adams, 1987; Hogmark and Alander, 1983; Samyn et al., 2008; Yung-Li et al., 2005). An important task is to determine experimentally the local laws of wear-fatigue damage and its prediction.

2. WAVE-LIKE DAMAGES

The tribo-fatigue system roller / shaft undergoes a mechano-rolling fatigue, to a certain extent reproduce the operating condi-
tions of wheel / rail system. It was found a special type of limiting state: formation on the raceway residual wave-like damages during such tests. Let’s look at the results of the experimental analysis of this phenomenon (Sosnovskiy et al., 2014; Sosnovskiy and Shcharbakou, 2005; Turin and Sherbakov, 2005). Tested for mechano-rolling fatigue was a tribo-fatigue system 25XGT steel (roller)/0.45 carbon steel (shaft). Properties of steel 25XGT were as follows: the fatigue limit \( \sigma_{f1} = 570 \text{ MPa} \), the rolling fatigue limit \( p_f = 3100 \text{ MPa} \). Properties of 0.45 carbon steel were as follows: the fatigue limit \( \sigma_{f2} = 260 \text{ MPa} \), the rolling fatigue limit \( p_f = 1760 \text{ MPa} \). Thus, the characteristic feature of the tribo-fatigue system was that the strength of the shaft’s metal is substantially less than the roller’s metal so during testing it was detected residual deformation and damage only in the vicinity of the raceway on the shaft, whereas the roller dimensions remain substantially undistorted.

Bending load \( Q = 225 \text{ N} = \text{const} \) corresponds to the stress amplitude \( \sigma_{st} = 225 \text{ MPa} < \sigma_{f2} = 260 \text{ MPa} \). Contact load was varied stepwise on program, shown in Fig. 3. Rolling fatigue limit \( p_f = 1760 \text{ MPa} \) was exceeded at the III stage of loading.

Motion of the roller on the shaft was unsteady in the transition from VII to VIII stage of contact loading, i.e. after 700 000 cycles of testing (see arrow 1 in Fig. 3). Residual radial deformations of the shaft in the area of non-stationarity are shown in Fig. 4 as bright points (750154 loading cycles, i.e. in the middle of the stage VIII). There was a loss of stability of motion at the IX stage (see arrow 2 in Fig. 3). Residual radial deformations of the shaft at the loss of stability of motion are shown in Fig. 4 by the crosses (851688 load cycles, i.e. in the middle of the stage IX). The tests were terminated at the X stage at \( N_2 = 976100 \) load cycles due to unacceptable vibration and noise. Deformations of the shaft after the tests are shown in Fig. 5 and 6.

What are the main features of damage for the shaft? The somewhat peculiar frozen waves of surface plastic deformation are formed on the raceway. They represent a set of irregular holes half-barrel-shaped. None of the wells is not repeated, each of them has its own, different from other sizes in all three dimensions – radial, axial, circumferential. The relative magnitude of plastic deformation (in this experiment) reaches 10% in radial direction and 30% in the axial ones.
in different "points" in the path of motion (Fig. 7). The strength of the material evaluated, e.g., hardness, is significantly different in these points, both before and after the test (Fig. 8).

![Fig. 8. Surface wave-like residual damage (chipping holes are blackened) (a) and microhardness distribution along the length L of the shaft raceways (b)](image)

3. THE CHARACTERISTICS OF LOCAL DAMAGE

Since there is a method of experimental measurement of local damages and some experience of their useful analysis, it was suggested several characteristics of local damage (Sosnovskiy et al., 2014). As you can see in Fig. 4 and 5 the next feature of the surface of local damage: if the circular contour of the test specimen is strictly symmetrical with respect to the center (to test), the contour of local damage, identifies eight measurement points (in these cases) is significantly asymmetric with respect to the same center (after the test).

![Fig. 9. The dependence of the coefficients Rα and ηα from the level of cyclic stresses in the test of 0.45 carbon steel / steel 2SKGT tribo-fatigue system on mechano-rolling fatigue at step changing of bending load (and, therefore, the stress amplitude σm) in the contact pressure p0 = 0.7pF = const. are shown in Fig. 9. It can be seen that the unevenness degree of local wear-fatigue damage increases respectively increasing of cyclic stresses. Note that the unevenness of wear-fatigue damage is greater, the smaller the values Rα and ηα.](image)

It was established experimentally geometry elements and precision in contact are factors that largely shape the emergence of wave-like damage during testing mechano-rolling fatigue.

The degree of asymmetry generally increases with increasing test time and the integral damage. Let’s introduce special integral characteristics of the local process of wear-fatigue damage:

- **asymmetry factor**
  \[ R_α = \frac{1}{4} \sum_{i=1}^{4} \frac{r_{\min}(i)}{r_{\max}(i)} \]  
  where \( r_{\min} \) and \( r_{\max} \) are the smaller and a larger radii of the same sample diameter, and the coefficient of unevenness
  \[ η_α = \frac{r_{\text{sm}}}{r_{\text{larg}}} \]  
  where \( r_{\text{sm}} \) and \( r_{\text{larg}} \) are the smallest and the largest radii of the sample during one revolution.

The designations specified radii of the specimen, as well as the dependence of the coefficients \( R_α \) and \( η_α \) from the level of cyclic stresses in the test of 0.45 carbon steel / steel 2SKGT tribo-fatigue system on mechano-rolling fatigue at step changing of bending load (and, therefore, the stress amplitude \( σ_m \)) in the contact pressure \( p_0 = 0.7p_F = \text{const.} \) are shown in Fig. 9. It can be seen that the unevenness degree of local wear-fatigue damage increases respectively increasing of cyclic stresses. Note that the unevenness of wear-fatigue damage is greater, the smaller the values \( R_α \) and \( η_α \).

It can be used technique of a determination of the asymmetry factor and coefficient of unevenness, namely, write them on the values \( δ_\alpha \):
Local Damages During Rolling and Mechano-Rolling Fatigue for the Mechanical System Shaft – Roller (0.45 Carbon Steel – 25XGT Steel, 20XH3A Steel – 20XH3A Steel)

\[ R_\delta = \frac{1}{4} \sum \frac{\delta_{\min}(i)}{\delta_{\max}(i)} \]

\[ \eta_\delta = \frac{\delta_{\lim}}{\delta_{\text{larg}}} \]  

(3)

It is easy to see that the coefficients defined by the formulas (3) is not equal to the corresponding coefficients are determined by formulas (1) and (2). The choice of representation of the coefficients \( R \) and \( \eta \) is dictated by the specific objectives of the analysis.

The experiment showed that it is possible to detect single and associated local damages: last interconnected raceway. Formation pronounced single local damage shown in Fig. 10. It is easy to understand that the "solid" wavy-like damage is the final stage of development of local damage from a single to associate ones and then to troppy phenomena.

Fig. 9. Dependence of the asymmetry factor and coefficient of unevenness from the level of cyclic stresses in the test of 0.45 carbon steel / steel 25XGT tribo-fatigue system on mechano-rolling fatigue at step changing of bending load in the contact pressure \( p_0 = 0.7p_f = \text{const.} \), right figure is a diagram for explaining the definition of \( \eta_a \) and \( \delta_a \) parameters according to the formulas (1) and (2).

Fig. 10. The convergence of axes in 8 points on the raceway depending on the number of cycles of multistage (I, II, ..., X) loading of the roller (steel 25XGT) – shaft (0.45 carbon steel) system during testing on mechano-rolling fatigue

If the limiting state is associated, for example, with a depth \( h \) of local damage \( \delta_{\lim} = h \), it is possible to construct a kind of fatigue curves on the criterion of local damage (Fig. 11) (Sosnovskiy et al., 2014). The numbers 1, 2, ..., 8 are designated the points on the perimeter of the raceway, which reached the limiting state \( (\delta_{\lim} = h) \) for the appropriate number of cycles \( N \). Sequence analysis of the location of the points 1, 2, ..., 8 leads to the conclusion that they are placed randomly on the graph. This conclusion does not contradict the known statistical mechanical fatigue test results of specimens: scattering increases with decreasing load. We emphasize, however, that the scattering region durability at every level of the stress is determined by the test results for only one pair of friction.

Come to the analysis of the data presented in Fig. 11, from a different perspective, let us build fatigue curves for each of the eight points individually (Fig. 12). Then the solid lines in this figure are local fatigue curves, each of which describes the limiting state at a specific point of the perimeter raceway. Thus, the Sosnovskiy – Bogdanovich – Yelovoy local fatigue curves (see Fig. 11 and 12) describe the heterogeneity of physical and mechanical properties in local areas of the test solid.

Fig. 11. The rolling fatigue curve for the roller (steel 25XGT) – shaft (0.45 carbon steel) system constructed on criterion of local damage

To learn the basic laws of formation and development of local damages, we dramatically increase the number of points of measurement (Fig. 13). The roller / shaft system made of steel 20XH3A is tested, and initial average hardness of the rolling surface was almost the same for both elements. The test results are shown in Fig. 14 and 15. It is clearly visible both single and associated local damages (Fig. 14) and wave-like damages – in Fig. 15.

The results of statistical processing of random values of local damage (radial residual strain) are shown in Fig. 16 on normal probability paper (in coordinates of the radial permanent deformation \( h \) – the probability \( P \) corresponding to the normal distribution law). Tab.1 shows the numerical values of the minimum \( (h_{\text{min}}) \), average \( (h) \) and maximum \( (h_{\text{max}}) \) strain of the roller (diameter \( d = 100 \text{mm} \)) and a shaft (diameter \( d = 10 \text{mm} \)).

Analysis of the data presented in Fig. 15 and 16 allows us to make the following general and unexpected conclusion: under these friction conditions the roller with diameter of 100 mm is systematically damaged significantly stronger than the shaft.
with diameter of 10 mm; ratio values for said objects varies in 2-10 times.

Fig. 12. The local rolling fatigue curve for the roller (steel 25XGT) – shaft (0.45 carbon steel) system

Explanation of this fact can’t be given to the theory of the scale effect; it suffices to recall that for 1 turn of roller the shaft gets 10 turns (cycles of loading). This means, for example, that when the contact load $F_N = 719$ N the shaft was $2 \cdot 10^7$ loading cycles (base of test), and the roller was only $2 \cdot 10^6$ cycles. Similarly, when at $F_N = 809$ N the shaft was $2.4 \cdot 10^6$ loading cycles (base of test) and the roller was only $2.4 \cdot 10^5$ cycles. The friction path for both elements was the same at specified load.

Thus, for equal path friction roller (diameter 100 mm) reaches the limiting state on criterion $\bar{h} = 84$ and $82 \mu m$ at the test load $F_N = 719$ N and 809 N (see Fig. 15), while the shaft (diameter 10 mm) reaches the average damage total only $\bar{h} = 12$ and $24 \mu m$ respectively.

4. CONCLUSION

1. Based on the analysis of experimental results of mechanical system shaft - roller for the 0.45 carbon steel, 25XFT, 20XH3A steels basic laws of wear-fatigue damage are installed: discrete, uneven and irregular occurrence and development of entry wear-fatigue damage; the formation of wave-like residual damage during echano-rolling fatigue (and rolling friction) due to excitation of shock-cyclic loading (troppy phenomenon, this phenomenon is typical for the exploited railway and tram rails); reduction of asymmetry factor and the coefficient of unevenness for wear-fatigue damage with time trials and with increasing levels of loading; initiation of emergence and development of wear-fatigue damage in the local areas in which the minimum strength of the material is detected.

2. To build the local fatigue curves describing the limiting state in a particular point of the perimeter of the dangerous section of the test mechanical system shaft – roller it is proposed. Such local rolling fatigue curves on the parameter of the wear limit for the shaft (steel 20XH3A) - roller (steel 20XH3A) are constructed.

3. Special integral characteristics of wear-fatigue damage the asymmetry factor and coefficient of unevenness are suggested.

Search for different causes of damage such two elements (of different diameters) of one pair of friction, provided that the surface hardness of the rolling surfaces for both elements substantially identical led to the hypothesis: the shaft is less damaged than the roller because it is bent during the test, whereas the roller is not. In fact, measurements have shown that in the plane of the contact load shaft deflection reaches 100 µm at $F_N = 809$ N and 70 µm at $F_N = 719$ N. This, apparently, is that some of the applied load “costs” not on the contact damage buton bending of the shaft. It follows that it is excited in bending moment counteracting to load $F_N$. In other words, it appears that the load applied to the conditions of this experiment as it is divided into two components: one of them causes surface damage on the raceway of shaft, and the other causes it bend.
